ABSTRACT

For security reasons, more and more digital data is transferred or stored in encrypted domains. In particular for images, selective format-compliant JPEG encryption methods have been proposed during these last ten years. Since the encryption is selective, in order to reduce the processing time and to be format-compliant, it is thus now necessary to evaluate the confidentiality of these selective crypto-compressed JPEG images. It is known that image quality metrics, such as PSNR or SSIM, give a very low correlation with a mean opinion score (MOS) for low quality images. In this paper, we propose an efficient confidentiality metric based on the visual saliency diffusion. We show experimentally that this metric is well correlated with a MOS and efficient to evaluate the confidentiality of selective crypto-compressed JPEG images.

Index Terms— JPEG, confidentiality metric, visual saliency, encryption

1. INTRODUCTION

With the increasing use of social media, more and more pictures are spread, shared and exchanged on the internet. Image quality assessment is divided in two main fields, no reference image quality assessment (NR-IQA), which refers to cases where only the processed image is available, with no extra information, and full reference image quality assessment (FR-IQA), where both the processed and the original images are available.

The PSNR is the most well known metric, but has been shown not to be well correlated with the human visual system (HVS), especially on low quality images. The SSIM [1], even if better correlated with the HVS, is not consistent across the whole range of image quality. Similar metrics [2–5] exhibit the same deficiencies, either on low or high quality images, as shown in [6]. There is not yet a confidentiality metric that consistently rates images across all the MOS spectrum. Most quality metrics fail to predict a MOS on low quality images, precisely where it would be most important to do so: decide whether or not an image is confidential. Confidentiality means that a HVS cannot understand the image content

The most popular image compression standard is JPEG [7]. In order to exploit both efficient compression and encryption, format compliant methods are designed to produce content compatible with format specifications. There exists several format compliant JPEG encryption methods which can be used in this context. Selective encryption methods using sign encryption have been shown insecure by Said [8]. Selective encryption can be applied on faces [9]. This method which relies on XOR operation with the AES algorithm, performs the compression and the encryption in the same process. Selective encryption is sufficient to hide sensitive information, such as text [10]. Moreover, it has the advantage to not change the size of the encrypted file. A reversible watermarking method in encrypted domain has been proposed by Qian *et al.* [11]. This method relies on XOR operation but for more visual masking, authors encrypt also quantization table. Block and coefficient scrambling is used in [12–15]. Simple scrambling methods tend to increase the size if there is no verification of the run-length for example. Inter-block shuffle and non-zeros AC scrambles methods have been shown insecure to sketch attack by Li and Yan [16].

This paper presents a full reference perceptual metric based on visual saliency which assesses image confidentiality after encryption or alteration for example.

Section 2 presents the dataset we used and how it was created. Then, in Section 3, we discuss the evaluation and rating of its images, by human (MOS) as well as by image quality metrics. In Section 4, we present the proposed metric for image evaluation based on the visual saliency. Finally, we conclude and open a few perspectives in Section 5.

2. CREATION AND UTILIZATION OF THE DATASET

The crypto-compression method we used is targeted towards JPEG images. We have six parameters that we can enable or not to generate selective crypto-compressed images. *Shuffle* and *XOR* are the parameters that decide the actual encryption method. *AC* and *DC* control which part of the DCT coefficients is encrypted and two additional parameters, *chrominance* and *luminance* decide which of the luminance, chromi-

nance (or both) DCT coefficients is encrypted. There must be at least one encryption method, at least one type of coefficient, and chrominance or luminance selected for the image to be affected. This results in 27 combinations obtained by combining these parameters. The distortions range from completely indecipherable images to almost invisible perturbations, as shown in Fig.1. This way, we can generate to have appropriate distortions for different use-cases as well as a wide range of distortions to show that different perturbations result in the same level of degradation.

The *XOR* parameter corresponds to the selective crypto-compression method proposed by Puech *et al.* [17]. This can be useful for low resolution visualization and it has two main strengths: it does not increase the size of the JPEG bit-stream and it changes the DCT coefficients histogram. We encrypt the amplitude part of non null AC coefficients *i.e.* the concatenation of the amplitude of each coefficient of each block $[A_0^i, \dots, A_k^i, \dots, A_0^n, \dots, A_k^n]$, where n is the number of blocks. The amplitude sequence is denoted $A = [a_0, \dots, a_l]$ where l is the number of amplitude bits. A standard stream cipher function is used to generate a pseudo-random sequence $E = [e_0, \dots, e_l]$ from a secret key. This sequence is XORed with the incoming plaintext to produce a ciphered sequence $\tilde{A} = [\tilde{a}_0, \dots, \tilde{a}_l]$ where $\tilde{a}_i = a_i \oplus e_i, i \in [0, l]$. The encrypted sequence is substituted to the amplitudes in the original bit-stream.

The *shuffle* parameter corresponds to a full inter-block shuffle (FIBS), proposed by Li and Yuan [16]. This method scrambles DC coefficients as well as same frequency AC coefficients. As it scrambles all coefficients, run length encoding does not perform as well and the size of the image can increase. According to the authors, the use of all AC coefficients, zero as well as non-zero, creates a more secure image, less sensitive to jigsaw puzzle attacks.

We used 200 images from the BSDS500 [18] dataset as our input images for a total of $27 \times 200 = 5400$ crypto-compressed images, each image named after the parameters used for its creation and its original name. The dataset is available at [].

3. IMAGE EVALUATION

A mean opinion score is an arithmetic mean of ratings given by humans for a particular stimulus. It is a single number, generally from 1 to 5, used to describe the quality of the current stimulus, where 5 is the best score and 1 is the worst. We conducted our evaluation on 41 different people using the following scale:

- 1: The distortion is unbearable, nothing is visible
- 2: The distortion is very annoying, I can barely guess the content
- 3: The distortion is annoying, but I can see the content
- 4: The distortion is slightly annoying, but the content is clear
- 5: The distortion is not annoying at all

A score of 1 corresponds to a fully confidential image, where no information about its content is available while a score of 5 corresponds to an image with no apparent distortion.

An example of the five values for this MOS is illustrated Fig. 1. The participants had to rate 81 images picked up randomly from the proposed database, three for each distortion. The sessions were 10 to 15 minutes long, depending on the person. The distortions order was shuffled differently for each evaluation.

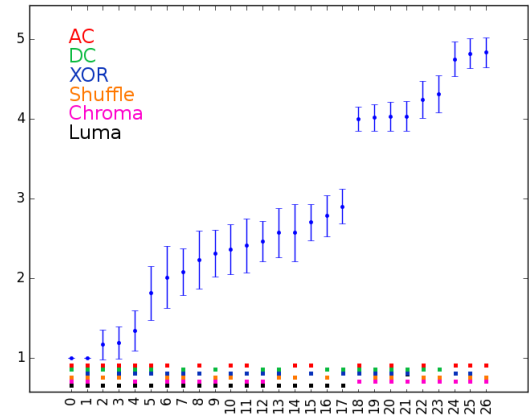

Fig. 2: MOS for the 27 distortions.

The images were evaluated in a dim room, on a 3840×2160 , 75 inches Sony screen, about 2.5 meters away and around eyes level. The user could only see one image at a time, a new image shown once the previous had been rated. The MOS obtained during the evaluation are given Fig. 2. We can see that after distortions #17 there is a large gap in the MOS. This is due to the absence of the parameter *luminance*, the *shuffle* and *XOR* are only performed on the chrominance, hence the better ratings. We give an overview of a few selected metrics we used for image analysis. For a more in-depth review, we refer the reader to [6].

PSNR: Even though it is known that the PSNR is not well correlated with human judgment, it is still widely used due to its speed and ease of use. The range is $[0; +\infty[$, where two identical images would have a PSNR of $+\infty$.

SSIM [1]: (Structural Similarity Index Measure). A luminance score, a contrast score and a structure score are combined to obtain the actual SSIM score. It has a range of $[0;1]$ where identical images have a score of 1.

ESS [19]: (Edge Similarity Score). It uses non overlapping 8×8 block directions to compare images. With the range $[0;1]$, a higher score reflects a less distorted image.

LSS [19]: (Luminance Similarity Score). It uses non overlapping 8×8 block average luminance to compare images. With the range $[-8.5; 1]$ for default parameters of $\alpha = 0.1$ and

Fig. 1: Example of images for different selective encryption methods with their corresponding MOS

$\beta = 3$, a higher score reflects a less distorted image.

NPCR [20,21]: It is the number of pixel changes between images. Its range is $[0;100]$, where a fully encrypted image has a NPCR close to 100, where almost all the pixels changed.

UACI [20,21]: It is the unified averaged changed intensity. It is the average intensity difference between two images. Its range is $[0;100]$, where a fully encrypted image has a value close to 33.

Our goal is to predict which rating a human would give to an image. In the best case scenario, a metric would be totally correlated with human rating and could be used to completely replace humans in image evaluation, this is however not the case, as shown in Fig. 3.

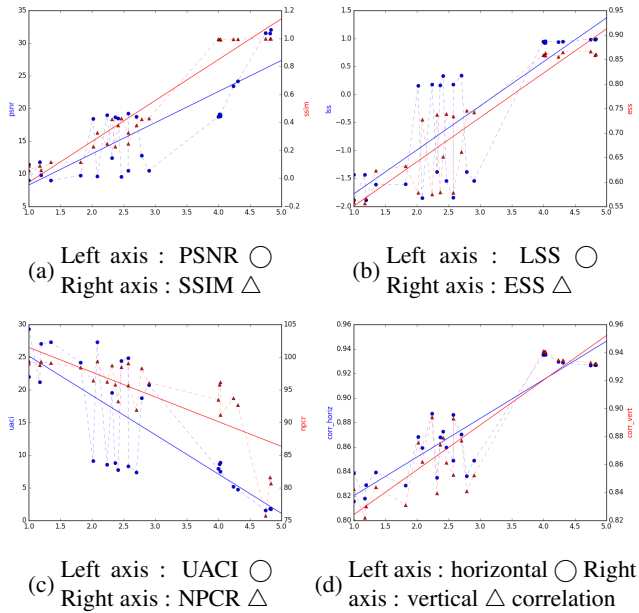

Fig. 3: Plots of different metrics with the MOS on the x-axis, 3a: PSNR and SSIM, 3b: LSS and ESS, 3c: UACI and NPCR, 3d: horizontal and vertical correlation

As we can see from Fig. 3, most metrics actually follow a rough line, but distortions 5 to 17 are problematic and prevent

us from predicting the MOS. These distortions also happen to be between a MOS of 2 and 3, where the threshold for a confidential image would be. Even the SSIM, which is the most accurate metric in our experiment, fails to predict the MOS.

4. VISUAL SALIENCY AS A MEANS TO EVALUATE IMAGE

In this section, we present the new metric we designed, results obtained and we analyze them. Our metric is based on the visual saliency in images, and saliency map. The visual saliency is interesting in our case for image quality assessment because we want to know whether the meaning of the content of an image is understandable. According to [22], important information is located in salient areas. Our reasoning is twofold: if salient areas are consistent in both the original and the processed image, the same amount of information is present in the images and the content is readily available, and if no salient areas can be found then the content is hidden. We try to compute to which extent the visual saliency of two images are similar to extract a score.

Let M_o be the saliency map of the original image and M_c be the saliency map of the crypto-compressed image. A threshold is applied to M_o and M_c to only keep the most salient areas of each image, the best threshold has been experimentally found (Fig. 5a) to be 15% more salient areas, it is the point with the highest correlation with the MOS. Two binary images are thus created, B_o from M_o and B_c from M_c . A first value is computed as such:

$$v_{saliency} = \frac{\sum_{i=0}^{width} \sum_{j=0}^{height} B_o(i, j) \times B_c(i, j)}{sum(B_o)}, \quad (1)$$

where $B_o(i, j) \times B_c(i, j)$ is equal to 1 when both pixels are equal to 1 and $sum(B_o)$ is the number of pixels of value 1 in of the original image.

Fig. 4: Global noise caused by a XOR on DCT coefficients.

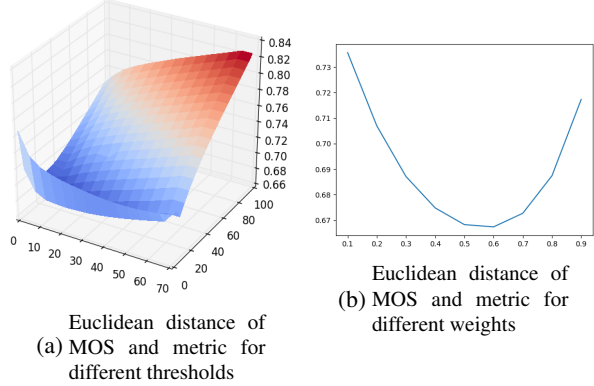

Fig. 5: Plots of different parameters to determine the best ones.

The proposed metrics as gives good results for either high or low quality images, where it is able to predict the MOS. The results are however not as good for mid quality images, when the MOS is around 2 and 3. Because of this, we can only tell that an image is either fully confidential or not very to not confidential at all, but not to which degree it is confidential.

This is due to the fact that we are not able to compute a meaningful saliency map on images with a global, patterned noise, such as such as an XOR on the DC coefficients of the luminance channel for example (Fig. 4a). Another problem we encountered is that the visual saliency performs too well on distorted images where the global structure is intact but the fine grained details are not available, typically when an XOR is applied to the AC coefficients of the luminance channel (Fig. 4b).

Because of these two types of distortions, and their variations, using only the visual saliency is not a realistic approach for an image confidentiality metric. We introduce a second score, v_{edges} , based on the Sobel operator [23] in an attempt to stabilize our first score.

Distortions such as Fig. 4a do not hinder the edges detection, making it a good candidate to balance the visual saliency defects. Our second score is computed the same way as our first one: two maps S_o and S_p are computed using the Sobel operator for the original and processed image. A threshold is then applied to S_o and S_p to only keep the strongest edges,

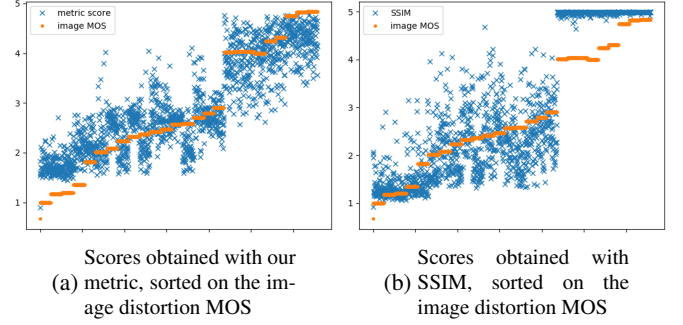

Fig. 6: Comparison of results for our metric and SSIM

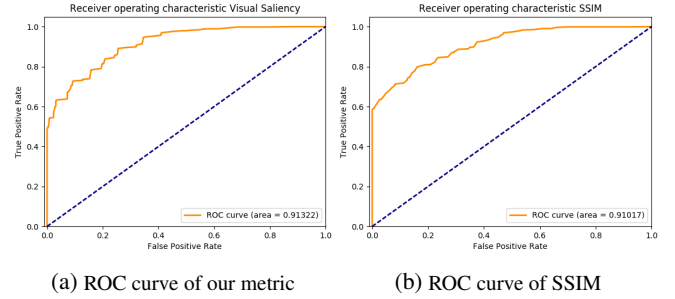

Fig. 7: ROC curves of our metric and SSIM.

thus creating two other bitmaps, the threshold has been experimentally found to be 10% of the edges (Fig. 5a). Our second score is then obtained just like Eqn 1, it is the ratio of the number of same position pixels of value 1 in both bitmaps over the total number of pixels of value 1 in the bitmap of the original image. The final score is $v = \alpha * v_{saliency} + (1 - \alpha) * v_{edges}$. The weight α was experimentally determined to be 0.6, as shown in Fig. 5b.

The results we obtained after running our metric on our dataset are available Fig. 6a, with Fig. 6b, the SSIM, for comparison. The euclidean distance of our metric to the MOS of every distortion is 0.4323 for our metric and 0.5095 for SSIM and the euclidean distance of our metric to individual image rating is 0.6674 and 0.6699 for SSIM.

The threshold for a confidential image would be between a MOS of 2 and 3. We used our metric as a classifier to try and decide whether images are confidential, the results are available Fig. 7.

5. CONCLUSION

In this paper we proposed a dataset composed of selective encrypted images for automatic image quality assessment. The images were rated by human observers to obtain a mean opinion score. We also introduced a new image quality metric based on the visual saliency. Our dataset was used as a benchmark to evaluate our metric and we saw that we obtained re-

sults at on par with the SSIM.

Future work would be a more in depth analysis of our dataset and each of its 27 distortions, as well as a more refined metric based on the visual saliency, which showed great potential.
